Abstract

Sotos syndrome is inherited in an autosomal-dominant manner and is characterized by increased birth weight, excessive growth, advanced bone age, and distinctive facial features, including dolichocephaly, hypertelorism, and a prominent mandible. We treated a jaw deformity due to Sotos syndrome consisting of malocclusion due to a narrow maxillary dental arch and mandibular retrusion from hypoplasia of the rami. The patient was a 17-year-old man. Malocclusion due to a narrow maxillary dental arch and mandibular retrusion was diagnosed. Rapid maxillary expansion with Lines corticotomy and mandibular advancement with distraction osteogenesis were performed. The maxilla was expanded laterally a total of 3 mm and the mandible prolonged 12 mm in the posterior area of the mandibular body. Subsequently, orthodontic treatment was continued. At present, 5 years after surgery, occlusion remains good and stable.

Key words: Sotos syndrome — Orthognathic treatment — Distraction osteogenesis

Introduction

Sotos syndrome, also known as cerebral gigantism, is a congenital disorder that was first reported by Sotos et al. in 1964[1]. Sotos syndrome is inherited in an autosomal dominant manner and is characterized by accelerated growth starting in the fetal period, a large head, dolichocephaly, frontal bossing, a high-arched palate, mandibular prognathism, large hands and feet, down-slanting palpebral fissures, ocular hypertelorism, strabismus, and nystagmus. Seizures and malignant tumors may also occur. Dyskinesia is usually not seen,
but mental retardation does occur, although the degree of intellectual impairment varies among patients \(^{1–3,8}\).

The treatment of a patient with Sotos syndrome who had malocclusion due to a narrow maxillary dental arch and mandibular retrusion caused by hypoplasia of the mandibular rami is reported. Orthognathic surgery including mandibular distraction was performed.

**Case**

The patient was a 17-year-old man who was evaluated for orthodontic treatment at our hospital at age 14 years with the chief complaint of malocclusion and functional dysphonia \(^{13}\). Sotos syndrome was diagnosed based on tall stature, typical facial abnormalities and developmental delay in infancy. The patient was treated for dental caries and the occlusal relationship examined. At age 16 years, malocclusion due to a narrow maxillary dental arch and mandibular retrusion was diagnosed. He was referred to our department of oral and maxillofacial surgery for orthognathic surgery (Figs. 1–3). His medical history was significant for Sotos syndrome, seizures, and hydronephrosis (surgeries at age 1 year 6 months and 3 years). The patient was on anticonvulsant therapy and had mild mental retardation. There was no family history of the syndrome.

On evaluation, his height was 185 cm and weight was 52 kg. Facial examination revealed dolichocephaly, left-right symmetry, maxillary protrusion, and mandibular retrusion. Occlusion was Angle Class II, with overjet of 14 mm and overbite of −1 mm. There was open bite, with crossbite in the molar region. The results of laboratory studies, including blood tests, electrocardiogram, and pulmonary function tests, showed nothing remarkable. Cephalometrics demonstrated maxillary protrusion and mandibular retrusion with an SNA of 73° and SNB of 68°. Lower facial height was increased, and the facial axis and depth were decreased.

The diagnosis was malocclusion due to mandibular retrusion caused by hypoplasia of the mandibular rami and a narrow maxillary dental arch. Rapid maxillary expansion combined with corticotomy and mandibular advancement with distraction osteogenesis was planned. The surgical treatment plan was explained to the patient and his mother and informed consent obtained.

**Treatment and Clinical Course**

Since the seizures were well controlled and cardiac function normal, surgery under general anesthesia was deemed possible after consultation with the attending internist and dental anesthesiologist. Therefore, at age 16 years, preoperative orthodontic treatment was started. At age 17 years, Lines cortico-

Maxillary protrusion and mandibular retrusion were revealed.
tomy (Le Fort I type) was performed under general anesthesia (Fig. 4). During surgery, the pyriform aperture was identified by an incision in the maxillary vestibule, and the inferior part of the nasal mucosa dissected. The cortical bone from the subzygomatic crest to the lateral margin of the pyriform aperture was then cut with a bone saw. In addition, the pterygomaxillary raphes were separated with a chisel. Next, the mucosa in the midline of the palate was stripped in a tunnel-like fashion with a periosteal elevator, and the median palatine raphe and anterior nasal spine separated with a bone saw and chisel. After mobility of the left-right bone segments was confirmed, the mucosa was sutured and closed. Operative time was 40 min, anesthesia time 1 hr 50 min, and blood loss 30 ml. There were no intraoperative complications, and the postoperative course was stable, without seizures or wound infection. On postoperative day 8, the patient was discharged. On day 14 after surgery, a rapid maxillary expansion device (skeleton type) was fitted and the maxilla expanded laterally a total of 3 mm at a rate of 0.5 mm per day over 6 days (Fig. 5).

At age 19 years, when preoperative orthodontic treatment was completed, mandibular distraction osteogenesis was performed under general anesthesia. Using a 3-D plaster model based on preoperative computed tomography, the insertion position of the mandibular distractor was established. Transnasal endotracheal intubation was performed under general anesthesia with propofol and fentanyl and application of vecuronium for muscle relaxation. General anesthesia was maintained with a target-controlled infusion of propofol at a predicted blood concentration of 3.0–5.0 μg/ml with nitrous oxide and
oxygen. During surgery, a mucosal incision was made along the external oblique ridge of the anterior border of the mandibular ramus. Then, after stripping the periosteum from the lateral border of the mandibular ramus and exposing the bone surface, the distractor was adjusted and fixed with screws. After removing the distractors, the mandible was cut at these sites with a bone saw and transected with chisels while preserving the inferior alveolar neurovascular bundle. The distractors were then inserted again, mobility of the bone segments confirmed and suturing and closure performed (Fig. 6). Operative time was 1 hr 40 min, anesthesia time 2 hr 50 min, and intraoperative blood loss 30 ml. There were no intraoperative complications.

The patient was hospitalized for 8 days after surgery, after which he was discharged; his clinical course was stable, without seizures or wound infection.

Starting on postoperative day 8, distraction was performed at a rate of 1 mm daily (0.5 mm in the morning and evening) for a total of 12 mm over 12 days (Fig. 7). Thereafter, the distractor was left in place to maintain distraction. Subsequently, orthodontic treatment was continued. At 1 year 3 months after surgery, active treatment was completed, and a retainer inserted. At 1 year 6 months after surgery, the distractors were removed under general anesthesia. Osteogenesis of the distracted region was good. At present, 5 years 2 months after mandibular distraction, occlusion remains good and stable and the patient is doing well (Figs. 8, 9).

Discussion

Sotos syndrome, also known as cerebral gigantism, is characterized by increased birth
weight, excessive growth during the first 4 years of life, advanced bone age, and distinctive facial features, including dolichocephaly, hypertelorism, and prominent mandible. With respect to maxillofacial features, dolichocephaly is almost always present, and increased mandibular length with pointed chin, highly-arched palate, and premature eruption of the deciduous teeth are observed in over 50% of such cases. In occlusion, there is a tendency for anterior crossbite with mandibular prognathism and maxillary retrusion.

Dolichocephaly, mild hypertelorism, a highly-arched palate, and a narrow mandibu-

lar dental arch were observed in the present patient. However, there was also mandibular retrusion due to hypoplasia of the mandibular rami, with lateral crossbite and anterior open bite.

According to recent studies, 80–90% of patients with Sotos syndrome had mutations and deletions of NSD1, which encodes a histone methyltransferase implicated in chromatin regulation. More recently, the NSD1 mutational spectrum has been defined. Cases of familial expression have been reported, but in the present patient the family history was unremarkable.

Patients with Sotos syndrome may have coexisting congenital heart and genitourinary anomalies, and careful attention must be paid to surgical planning. Patients may have attention deficit hyperactivity disorder, and intelligence can range from normal to severe mental retardation. Surgery for scoliosis and intensive dental treatment under general anesthesia in such patients has previously been reported. To our knowledge, however, no reports have been published on aggressive orthognathic surgery including distraction osteogenesis in such cases, possibly due to the factors described above. In patients with skeletal malocclusion, though, improvement of bite with orthognathic surgery is effective not only for masticatory function, but also for prevention of dental caries and periodontal disease. If coexisting disorders are mild and surgery can safely be performed, this option should be considered.

Distraction osteogenesis, which was indicated in the present patient, involves applying an external force with gentle traction during the callus formation stage of fracture healing to promote osteogenesis between the bone segments to lengthen bone. Since being developed by Ilizarov in 1989, distraction osteogenesis has been widely used in orthopedics to lengthen limbs and for treatment of nonunion. In maxillofacial surgery, after Snyder et al. reported studies of mandibular distraction in dogs, McCarthy et al. performed mandibular distraction in patients with hemifacial microsomia and micrognathia.

Subsequently, mandibular distraction has been performed to treat a variety of conditions, and it is particularly useful in cases such as in the present patient where there are severe developmental defects of the mandible. Initially, transcutaneous extraoral devices were used, but recently many types of intraoral device that do not require a skin incision have become available. These can also be used for expansion of a narrow maxillary dental arch. These methods involve relatively little operative time and blood loss, but because a bulky device is inserted into the oral cavity, attention must be paid to oral hygiene during treatment. In addition, after surgery, the patients themselves must manipulate the distractor every day for a few days to a few weeks, depending on the amount of lengthening required. Therefore, patient and family cooperation is important. After distraction, long-term retention with distracters or metal plates is required to prevent relapse.

The present patient had mild mental retardation but could independently perform daily activities. Treatment went according to plan, with the help of good patient and family communication and thorough instruction on oral hygiene. Furthermore, careful planning of preoperative and postoperative management, including general anesthesia, was undertaken to prevent seizures during surgery. Currently, the mandibular position is stable, without any marked retrusion. Careful follow-up and oral hygiene will be needed to prevent dental caries and periodontal disease. In addition, the patient should be monitored for gingival hyperplasia, a possible side effect of anticonvulsant drugs.

**Conclusion**

Mandibular distraction may be indicated to improve occlusion in patients with Sotos syndrome associated with malocclusion caused by a narrow maxillary dental arch and mandibular retrusion. Patient and family cooperation throughout the often lengthy period that orthognathic treatment requires is particu-
larly important in patients with mental retardation, including during surgery, inpatient treatment, and oral hygiene management.
